Stress and asthma: Novel insights on genetic, epigenetic, and immunologic mechanisms

Stacy L. Rosenberg, MD,a Gregory E. Miller, PhD,b John M. Brehm, MD, MPH,a and Juan C. Celedón, MD, DrPHb
Pittsburgh, Pa, and Evanston, Ill

In the United States the economically disadvantaged and some ethnic minorities are often exposed to chronic psychosocial stressors and disproportionately affected by asthma. Current evidence suggests a causal association between chronic psychosocial stress and asthma or asthma morbidity. Recent findings suggest potential mechanisms underlying this association, including changes in the methylation and expression of genes that regulate behavioral, autonomic, neuroendocrine, and immunologic responses to stress. There is also evidence suggesting the existence of susceptibility genes that predispose chronically stressed youth to both post-traumatic stress disorder and asthma. In this review we critically examine published evidence and suggest future directions for research in this field.

(J Allergy Clin Immunol 2014;134:1009-15.)

Key words: Asthma, psychosocial stress, immune system, neuroendocrine system, genetics

Discuss this article on the JACI Journal Club blog: www.jaci-online.blogspot.com.

Asthma is a major public health problem in the United States, where approximately 25.7 million children and adults are currently living with asthma.1 In this country members of certain ethnic minority groups (eg, Puerto Rican and African American subjects) and the economically disadvantaged share a disproportionate burden of the ‘‘asthma epidemic.’’2

In the United States ethnic minorities and the economically disadvantaged are disproportionately exposed to chronic psychosocial stressors (eg, poverty, discrimination, and violence).3 A growing body of literature supports a causal link between exposure to these stressors at the individual or community level and asthma or morbidity from asthma in children and adults (recently reviewed by Yonas et al4). For example, physical or sexual abuse during childhood, a major stressor, has been associated with asthma or asthma morbidity in Puerto Rican school-aged children,5 as well as with adult-onset asthma in African American women.6 Moreover, a birth cohort study of 145 children with a maternal history of asthma found that parental difficulties in early postnatal life (at age 3 months) were associated with asthma at 6 to 8 years of age.7 In another birth cohort study including 708 children in Boston, prenatal exposure to community violence was associated with recurrent wheeze at age 2 years (a risk marker for asthma).8 Current evidence also suggests that the relation between stress and asthma is complex and partially mediated and modified by environmental exposures (eg, outdoor air pollution9 and cigarette smoking10), adherence to treatment, and coping mechanisms (eg, shift-and-persist strategies11 and family support).

Yet on top of these factors, stress is likely to affect the onset and course of asthma by directly acting on pathogenic mechanisms in the airways.11,12 Although these pathways have yet to be fully elucidated, preliminary evidence suggests a role for stress in modulating lung development, neuroendocrine and autonomic nervous system (ANS) responses, and the immune system.4,13 Decades of research show that stressors, when perceived as threatening and unmanageable, modify the activity of the hypothalamic-pituitary-adrenocortical (HPA) axis and the immune system.14

Abbreviations used

ANS: Autonomic nervous system
aOR: Adjusted odds ratio
CRH: Corticotropin-releasing hormone
HA: Handling stimulation
HPA: Hypothalamic-pituitary-adrenocortical
MS: Maternal separation
PACAP: Pituitary adenylate cyclase–activating polypeptide
PTSD: Post-traumatic stress disorder
SES: Socioeconomic status
SNP: Single nucleotide polymorphism

norepinephrine, and acetylcholine. By changing the outflow of these systems, stress alters the systemic balance of glucocorticoids and catecholamines, as well as concentrations of these (and other) hormones in primary and secondary lymphoid organs. Macrophages and lymphocytes have functional receptors for these hormones (glucocorticoid receptors for cortisol and α- and β-adrenergic receptors for catecholamines), and ligation of these receptors alters these cells’ repertoires of gene expression, with downstream implications for trafficking, signaling, proliferation and differentiation, and effector functions. Through these modulatory influences, chronic stressors potentiate reactivity to asthma triggers, such as allergens and infections, and in doing so might exacerbate airway inflammation and airflow obstruction.

More recently, mechanistic research in this area has begun to focus on the role of allelic variation in genes that regulate stress responses, as well as stress-induced changes in DNA methylation patterns and gene expression. In this report we first review recent findings on potential biologic mechanisms for stress-related asthma (summarized in Table I), which might be modified by environmental and lifestyle factors, social support, or comorbidities, as shown in Fig 1. We then discuss future directions for research in this field.

**GENETICS, GENOMICS, AND EPIGENETICS OF STRESS AND ASTHMA**

As for other complex diseases, genome-wide association studies have identified common genetic variants that confer susceptibility to asthma but do not account for a large proportion of its heritability (phenotypic variation explained by genetic factors). This “missing heritability” of asthma might be explained by unaccounted phenotypic heterogeneity, rare genetic variants with strong effects, gene-gene interactions (epistasis), gene-environment interactions, or epigenetic mechanisms, such as DNA methylation or microRNAs. Few studies have examined the role of genetic or epigenetic mechanisms on stress-related asthma.

In a study of more than 1200 (predominantly African American) adults exposed to traumatic events, Ressler et al implicated the pituitary adenylate cyclase–activating peptide (PACAP)–PAC1 receptor pathway on the pathogenesis of posttraumatic stress disorder (PTSD). In this study both PACAP38 (PACAP peptide containing 38 residues) blood levels and the C allele of a functional single nucleotide polymorphism (SNP; rs2267735) in an estrogen-receptor element of the gene for the PAC1 receptor (ADCYAP1R1) were significantly associated with PTSD or more PTSD symptoms in female but not male subjects. For example, the correlation coefficient (r) for PACAP38 blood level and PTSD symptoms was 0.497 (P < .005) in female subjects but nonsignificant in male subjects (P > .5). In contrast to these sex-specific associations, methylation of a CpG site in the promoter of ADCYAP1R1 (assessed in DNA from white blood cells) was shown to be associated with PTSD or more PTSD symptoms (r for symptoms = 0.35, P < .0005). ADCYAP1R1 mRNA was shown to be inducible after fear conditioning in rodents, which further supports the plausibility of the human findings. A female-specific association between the C allele of rs2267735 and PTSD or PTSD symptoms has been replicated in studies of highly traumatized Chinese adults and African American adults but not in a study of adults of European or African American descent who were not selected on the basis of traumatic exposures. By using magnetic resonance imaging, the C allele of rs2267735 was recently shown to affect fear responses in the amygdala and hippocampus of women with lifetime history of exposure to traumatic events. Of interest, the C allele of rs2267735 was associated with anxiety in school-aged boys and girls, suggesting that any sex-specific effects of this SNP are not present before puberty. In contrast to the published work replicating an association between SNP rs2267735 and PTSD, findings for ADCYAP1R1 methylation have yet to be replicated for PTSD. Given that PTSD has been associated with asthma or asthma symptoms, there has been recent interest in studying both methylation and genetic variants in ADCYAP1R1 and asthma.

Puerto Ricans are disproportionately affected by asthma in the United States and often exposed to violence, both in the household and in the community. Our group has shown that physical/sexual abuse and parental stress are associated with asthma in Puerto Rican children. Given these findings, known increased susceptibility of Puerto Rican adults to having PTSD after exposure to traumatic events, and experimental evidence suggesting a potential role of ADCYAP1R1 in regulating expression of the glucocorticoid receptor gene, we examined exposure to violence (assessed by using a validated scale), ADCYAP1R1, and asthma in 516 Puerto Rican children aged 6 to 14 years. In this study we demonstrated that exposure to violence is associated with methylation of a CpG site in the promoter of ADCYAP1R1 (adjusted β value per each 10-point increment in the ETV scale obtained from a linear regression model, 0.5%; 95% CI, 0.1% to 0.9%; P = .02) and that such methylation is associated with asthma in Puerto Rican children (adjusted odds ratio [aOR] per each 1% increment in methylation obtained from a logistic regression model, 1.3; 95% CI, 1.0-1.6; P = .03). Moreover, we showed that the C allele of SNP rs2267735 (previously implicated in PTSD and anxiety) is associated with 30% increased odds of asthma (95% CI for aOR, 1.0-1.7; P = .03) in these children.

Our findings for ADCYAP1R1 have yet to be replicated, and we cannot exclude reverse causation for the methylation findings (eg, asthma leading to increased DNA methylation) in a cross-sectional study. However, the biological plausibility of our results is supported by experimental models showing that PACAP acts as an endogenous bronchodilator, relaxing airway smooth muscle. Moreover, PACAP protects against endotoxin-induced allergic airway inflammation in rodents, in which the PAC1 receptor mediates anti-inflammatory effects in allergic airway inflammation. Together with these experimental findings, our results suggest that genetic and epigenetic variation in a susceptibility gene for PTSD and childhood anxiety (ADCYAP1R1) is implicated in the pathogenesis of asthma in children disproportionately exposed to violence or traumatic events, such as Puerto Ricans.

CRH, along with signaling of PACAP, regulates anxiety-related behavior and is thus in a candidate pathway for stress-related asthma. SNPs in the gene encoding the main receptor for CRH (CRHRI) have been associated with change in lung function in response to inhaled corticosteroids in patients with asthma or chronic obstructive pulmonary disease in some studies but not in others.

Few studies have examined the effects of psychosocial stress on genome-wide expression in tissues relevant to asthma. In a

COPD, Chronic obstructive pulmonary disease; ICS, inhaled corticosteroid.

genome-wide study of transcriptional profiles from CD2⁺ T lymphocytes of 31 school-aged children, low socioeconomic status (SES; a stressor correlated with other stressors, such as exposure to violence) was associated with overexpression of genes regulating inflammation, including chemokine activity and cytokine production. In this small study results from a bioinformatics analysis offered preliminary support for a mediating role of cyclic AMP response element binding protein, nuclear factor Y, and nuclear factor κB on the observed effects.

Social adversity in early life might program biological systems in a manner predisposing to chronic diseases, such as asthma. In a study of genome-wide transcriptional profiles in PBMCs from 103 healthy adults aged 25 to 40 years, low SES in early life was associated with upregulation of genes bearing responses for the CREB/ATF family of transcription factors conveying adrenergic signals to white blood cells, as well as with downregulation of genes with response elements for the glucocorticoid receptor (which, as noted above, transduces cortisol’s anti-inflammatory effects in macrophages and lymphocytes). In this study low SES was also associated with overexpression of transcripts with response elements for nuclear factor κB and increased stimulated production of IL-6 (eg, PBMCs from subjects with low early-life SES produced 51% more IL-6 in response to Toll-like receptor 3 stimulation with the ligand polyinosinic-polycytidylic acid than did those with high early-life SES; P = .03). Taken together with those from other studies, these results suggest that low SES in early life programs sustained resistance to glucocorticoid signaling, ultimately leading to increased adrenocortical and inflammatory responses in adulthood. Among those who go on to have asthma, this programmed resistance might also undermine the efficacy of steroid therapy. Large longitudinal studies are needed to validate and expand on these findings.

STRESS, IMMUNE RESPONSES, AND ASTHMA

Findings from recent experimental studies suggest that stress might predispose to asthma or asthma morbidity through effects on the immune system. In an experimental model Fischer 344 rats were subjected to repeated handling stimulation (HA), maternal separation (MS), or no intervention at age 4 weeks. At age 5 months, HA rats had increased ex vivo natural killer cell cytotoxicity but no other alterations in immune responses. After...
induction of experimental asthma, MS rats had greater number of eosinophils in bronchoalveolar lavage fluid than control or HA rats (P = .002). In HA rats induction of experimental asthma was associated with markedly increased levels of adrenocorticotropin compared with that seen in the MS or control groups (P for 1-way ANOVA = .02). Taken together, these results suggest that early postnatal stressors have effects on the neuroendocrine immune system lasting into adult life.

Consistent with results from human studies, findings in rodents suggest that stress enhances the detrimental effects of environmental exposures on asthma. In particular, rats exposed to both concentrated ambient particles and stress had higher blood levels of C-reactive protein and TNF-α but lower lung function than those exposed only to either concentrated ambient articles or stress. For example, exposure to particulate matter of less than 2.5 μm in diameter was significantly associated with a lower peak expiratory flow in stressed animals (adjusted β value per each microgram per cubic meter increment = −3.9 × 10^{-3}, P = .003) but not in nonstressed animals (P = .92).

Because prenatal or early postnatal exposures are likely to have major effects on immune system development, there is considerable interest in studying whether stressors can lead to asthma development through alteration of immune responses in early life. However, the relationship between cytokine profiles in early life and asthma is insufficiently understood, and thus children participating in birth cohort studies must be followed up to age 6 years or greater, when asthma can be confidently diagnosed.

To date, published studies of prenatal and early postnatal stress and childhood asthma are lacking sufficient data on stress or follow-up of participants into school age. Nonetheless, emerging evidence suggests that maternal stress influences immune responses and asthma symptoms in infancy. For example, a birth cohort study of 557 inner-city children found that cumulative prenatal maternal stress was associated with cord blood mononuclear cell innate and adaptive cytokine responses. In this study prenatal maternal stress was associated with increased production of IL-8 and TNF-α after microbial stimuli, as well as with increased IL-13 production after dust mite stimulation and reduced PHA-induced IFN-γ levels (P < .05 in all instances). Postnatal family stress also seems to influence patterns of early-life immune response relevant to asthma. One birth cohort tracked parental stress levels every 2 months for the initial 24 months of the child’s life. In this study greater parental stress between ages 6 and 18 months was associated with a total IgE level of 100 IU/mL or greater (aOR, 2.0; 95% CI, 1.1-3.6; P < .05) and larger TNF-α production in offspring at age 2 years.

Early-life stress might lead to programming of neuroendocrine and immune responses in girls that is carried over to adulthood and to pregnancy and ultimately to the child’s development. A recent birth cohort study of 510 urban children showed that maternal low SES during childhood was directly associated with cord blood IgE level (adjusted β value from a structural equation model = 0.21, P = .003) and indirectly (through prenatal cumulative stress, low SES in adulthood, and air pollution) to recurrent wheeze in their children. In contrast to these findings, a cross-sectional study of 267 Canadian children found no difference in IL-6 production by PBMCs stimulated with LPS between children with consistently high SES since birth and those who experienced upward mobility (going from lower-middle-class to higher-middle-class status), suggesting that some programming effects of early-life stressors can be reversed. In contrast to children with an “upward SES trajectory,” those with persistently low SES had increased IL-6 production by stimulated PBMCs, particularly if they were overweight. In addition, atopic asthma was associated with a 54% increment in IL-6 level in urban children (P = .03) but was not significantly associated with IL-6 in rural children.

A 2-year prospective study of 147 children aged 9 to 18 years examined whether acute or chronic stress is associated with cytokine responses or asthma symptoms at school age. In this study acute stress was associated with increased cytokine (IL-4, IL-5, and IFN-γ) production by PBMCs after mitogenic stimulation but only in children with asthma and high levels of chronic stress. In this study chronic stress (particularly in the presence of acute stress) and IL-5 levels were associated with increased symptoms in a subset of 32 children with moderate-to-severe asthma (P < .05 in both instances). The main limitations of this study are limited statistical power to assess stress effects on multiple cytokines, the fact that acute stress could have occurred as early as 6 months before the study visits (because they were

FIG 1. Potential causal mechanisms for stress-related asthma or asthma morbidity.
and the genes encoding the glucocorticoid receptor (by 5.5-fold) and the β2-adrenergic receptor (by 9.5-fold) in leukocytes of children with asthma (adjusted P < .05 in both instances). In another study including 143 school-aged children, perception of low parental support was associated with reduced response to corticosteroids in vitro and higher circulating levels of eosinophil cationic protein in asthmatic children. In this study response to corticosteroids was assessed by measuring production of IL-5, IL-13, and IFN-γ by PBMCs (incubated with a mitogen cocktail) after adding physiologic doses of hydrocortisone. Although limited by a cross-sectional design, findings from the 2 studies referenced above support the hypothesis that chronic stress leads to downregulation of glucocorticoid receptor expression and function. Nevertheless, these findings must be substantiated with in vivo measurements of glucocorticoid sensitivity.

FUTURE DIRECTIONS

Development of novel indicators or biomarkers of chronic stress is imperative, given that currently used indicators of stress cannot be used in young children (eg, questionnaires) or are difficult to implement in large studies (eg, detailed interviews with parents and multiple measures of salivary cortisol to assess circadian rhythm). Measuring cortisol in hair is one potential strategy that has the advantage of capturing more chronic HPA axis activity as experienced over a several-month timeframe. Moreover, one could gain novel insights into stress-related asthma by examining the relation between chronic stress and gene expression and epigenetic changes in tissues relevant to asthma (eg, airway epithelium and lymphocytes).

Accounting for mediators and modifiers of the effect of stress on asthma is key in future longitudinal studies of stress and asthma or asthma morbidity. For example, which proportion of the effect of stress on asthma morbidity or treatment response is explained by reduced adherence to controller medications? To what extent does having coping mechanisms or social support attenuate the effects of stress on asthma? Does exposure to other environmental exposures (eg, cigarette smoking and air pollution) or comorbidities (eg, obesity) modify the effect of stress on asthma and, if so, to what extent? Does stress lead to epigenetic changes in tissues relevant to the pathogenesis of asthma? Do variants that confer susceptibility to stress-related mental illness or anxiety affect asthma (by themselves or interacting with stress) on populations at risk?

Phenotypic assessment of asthma and immune responses has been often overlooked in studies of stress and asthma. Sufficiently long follow-up of ongoing birth cohort studies, assessment of objective markers of disease severity or control (eg, pulmonary function tests and airway responsiveness), examination of subphenotypes of the “asthma syndrome” (eg, atopic vs nonatopic asthma and eosinophilic vs noneosinophilic asthma), and measurement of cytokine profiles other than TNF-α/TNF-β (eg, TNF-β) will be important in future studies of stress and asthma.

Studying the role of stress on treatment responses in vivo is a high priority. Does stress reduce the efficacy of treatment responses independently of adherence with medications? If so, is this mediated by downregulation of the glucocorticoid receptor? Are the effects of stress on treatment response (if any) more marked in populations exposed to heavily traumatic events?

In summary, there is compelling evidence for a link between chronic psychosocial stress and the onset and course of asthma. Over the past decade, there has been substantial progress identifying alterations in the HPA axis and the ANS, as well as immunologic mechanisms likely to underlie these phenomena. More recently, studies have begun to highlight specific signal transduction pathways through which stress modulates epigenetic and transcriptional activity in asthma-relevant cells and to identify susceptibility genes that might confer risk for stress-related exacerbations of asthma. Further understanding of these mechanisms will improve our capacity to prevent and treat asthma, particularly in vulnerable populations (eg, ethnic minorities and the economically disadvantaged) who experience disproportionate rates of the asthma burden in this country. Such progress could have a major effect in reducing unacceptable health disparities in asthmatic patients in the United States and worldwide.
